Abstract

Objective: To evaluate poly(GP), a dipeptide repeat protein, and neurofilament light chain (NFL) as biomarkers in presymptomatic C9orf72 repeat expansion carriers and patients with C9orf72-associated frontotemporal dementia. Additionally, to investigate the relationship of poly(GP) with indicators of neurodegeneration as measured by NFL and grey matter volume. Methods: We measured poly(GP) and NFL levels in cerebrospinal fluid (CSF) from 25 presymptomatic C9orf72 expansion carriers, 64 symptomatic expansion carriers with dementia, and 12 noncarriers. We explored associations with grey matter volumes using region of interest and voxel-wise analyses. Results: Poly(GP) was present in C9orf72 expansion carriers and absent in noncarriers (specificity 100%, sensitivity 97%). Presymptomatic carriers had lower poly(GP) levels than...
symptomatic carriers. NfL levels were higher in symptomatic carriers than in presymptomatic carriers and healthy noncarriers. NfL was highest in patients with concomitant motor neuron disease, and correlated with disease severity and survival. Associations between poly(GP) levels and small grey matter regions emerged but did not survive multiple comparison correction, while higher NfL levels were associated with atrophy in frontotemporoparietal cortices and the thalamus. **Interpretation:** This study of C9orf72 expansion carriers reveals that: (1) poly(GP) levels discriminate presymptomatic and symptomatic expansion carriers from noncarriers, but are not associated with indicators of neurodegeneration; and (2) NfL levels are associated with grey matter atrophy, disease severity, and shorter survival. Together, poly(GP) and NfL show promise as complementary biomarkers for clinical trials for C9orf72-associated frontotemporal dementia, with poly(GP) as a potential marker for target engagement and NfL as a marker of disease activity and progression.

**Materials and Methods**

**Subjects**

We examined CSF from 101 subjects from C9orf72 families, which was collected among eight sites (five sites participating in the Genetic FTD Initiative (GENFI), the University of California, San Francisco, the VU University Medical Center, and IRCCS Fatebenefratelli; Table S1). These CSF samples were obtained from 64 patients with dementia caused by the C9orf72 repeat expansion (symptomatic carriers), and 37 healthy first-degree family members of C9orf72 expansion carriers. The unaffected family members consisted of 25 presymptomatic C9orf72 expansion carriers and 12 noncarriers, and clinical investigators...
were blinded to mutation status. Family members were defined as unaffected if they had an absence of motor deficits, behavioral changes, and cognitive changes, as assessed by neurological examination, neuropsychological testing, and structured informant interviews (e.g., with a spouse or sibling). The presence of a pathogenic C9orf72 repeat expansion, defined as more than 30 repeats, was ascertained at the local sites. Symptomatic C9orf72 expansion carriers were diagnosed according to criteria for behavioral variant FTD (bvFTD, n = 47; 9 with concomitant MND)\(^1\) or primary progressive aphasia (PPA, n = 6; 2 with concomitant MND)\(^2\) at time of inclusion. Subjects with mild cognitive or behavioral symptoms who did not meet these diagnostic criteria for FTD were classified as having mild impairment (n = 9), and were included in the symptomatic carrier group. Among these nine subjects with mild symptomatology, seven had behavioral symptoms and two had memory symptoms. Lastly, two patients had dementia with a predominant memory presentation, without known behavioral or motor changes. ALS patients without cognitive or behavioral symptoms were not included in this study because the number of available subjects was too small to perform statistical analyses.

ALS patients with structural abnormalities (including extensive white matter hyperintensities or lacunar infarcts, n = 6; 2 with concomitant MND) were excluded from the NfL analyses. Among the longitudinally collected samples, NfL measurements were not performed on two because of insufficient CSF volumes.

For a given clinical subgroup (noncarriers, presymptomatic carriers, and symptomatic carriers), CSF NfL and poly(GP) levels did not significantly differ among the different centers at which CSF was collected.

**MRI acquisition and preprocessing**

T1-weighted MRI images (1.5 or 3 Tesla) captured within 3 months of CSF collection were included for imaging analyses (n = 72). After excluding poor quality scans (e.g., motion artifact, n = 6) and scans from subjects with structural abnormalities (including extensive white matter hyperintensities or lacunar infarcts, n = 3), scans were available for 63 subjects (11 noncarriers, 24 presymptomatic carriers, and 28 symptomatic carriers) from 11 different scanners across seven sites. The NfL level was unavailable for one symptomatic carrier. MRI images were analyzed using two methods: region of interest (ROI) analysis and voxel-based morphometry (VBM). For ROI analysis, scans were parcellated into brain regions as previously described,\(^{23}\) using an atlas propagation and label fusion strategy,\(^{24}\) combining bilateral ROIs to calculate grey matter cortical (frontal, temporal, parietal, occipital, cingulate, insular), subcortical (hippocampus, amygdala, caudate, putamen, thalamus), and cerebellar volumes.\(^{25,26}\) Whole brain volumes were calculated by combining all grey and white matter regions extracted from the automated brain segmentation method. All volumes were expressed as percentage of total intracranial volume (TIV), computed with SPM12 (Statistical Parametric Mapping, Wellcome Trust Centre for Neuroimaging, London, UK) running under Matlab R2014b (Math Works, Natick, MA).\(^{27}\) For the VBM preprocessing, T1 images were normalized using standard spatial normalization in SPM12 (http://www.fil.ion.ucl.ac.uk/spm/software/spm12/), modulated, corrected for non-linear warping, then segmented into grey and white matter images. Grey matter images were smoothed using a half-maximum isotropic Gaussian kernel with a size of 8 mm full-width chosen due to the heterogeneity of scanners in the study.
Statistical analysis

Statistical analyses were performed in SPSS 21.0 for Windows (Armonk, NY) and graphs were drafted with GraphPad Prism 7 (La Jolla, CA). Test statistics were considered significant at \( P < 0.05 \) (two-tailed). Since the poly(GP) concentrations were non-normally distributed, a log-transformation was applied after adding a constant of 0.1 to all values to avoid values of zero. CSF NfL was log-transformed to normalize the data; three samples with levels \( >10,000 \) pg/mL [all had concomitant MND with either bvFTD (\( n = 2 \)) or nonfluent variant PPA (\( n = 1 \)] continued to skew the data and were therefore set at 10,000 pg/mL prior to the transformation to allow further parametric analysis. Group comparisons of poly(GP) and NfL were first performed by Kruskal–Wallis (with Dunn’s post hoc tests) or Mann–Whitney tests on raw data, followed by ANCOVAs on log-transformed data with correction for age and gender. When longitudinal CSF samples were available, only the time-point close to MRI or the first time point was used in group comparisons. Area under the curve (AUC) with a 95% confidence interval (CI), obtained by receiver operating characteristic analyses, was used to examine diagnostic performance, with optimal cut-off levels at the highest (sensitivity + specificity)-1. Correlations with age at CSF collection, age at disease onset, disease duration, and cognitive scores were assessed with Spearman correlations on non-transformed data. Survival in patients was compared among tertiles of poly(GP) and NfL by Kaplan–Meier curves and Cox regressions adjusted for age, gender, presence of MND, and disease duration, with living patients included as censored data. The Cox regressions were also performed using poly(GP) or NfL as a continuous variable. Although we had a relatively small number of carriers with longitudinal samples (\( n = 10 \)), exploratory analyses on poly(GP) and NfL change were undertaken by calculating the annual change ((second concentration – first concentration)/interval between time points) and testing these values against zero using a one-sample Wilcoxon signed-rank test.

All imaging analyses were controlled for age at CSF collection, gender, scanner, and TIV. Linear regressions were used to explore the associations between transformed poly(GP) or NfL and the ROIs. VBM analyses were conducted in SPM12 using subjects’ smoothed, modulated grey matter segments. Within SPM’s general linear model framework, we used one-sample t-test designs in two separate analyses to correlate either log-transformed poly(GP) levels or NfL with grey matter volume among all C9orf72 expansion carriers. We repeated these correlations between poly(GP) and NfL with grey matter in presymptomatic and symptomatic expansion carrier subgroups. Results were regarded as significant at \( P < 0.05 \) family-wise error corrected for multiple comparisons (\( p_{\text{FWE}} \)). When associations were not significant at this threshold, a less stringent threshold of \( P < 0.001 \) was used. Mean raw grey matter intensities were extracted from regions showing significant results at \( P < 0.001 \) using the MARSBAR toolbox for SPM8,\(^{28}\) and plotted against poly(GP) and NfL concentrations for visualization purposes.

Results

Demographic and clinical data

In total, 64 symptomatic C9orf72 repeat expansion carriers, 25 presymptomatic expansion carriers, and 12 healthy noncarriers were included in our study (Table 1). The clinical phenotypes of the symptomatic carriers were: bvFTD (\( n = 38 \)), bvFTD-MND (\( n = 9 \)), subjects with mild impairment (\( n = 9 \)), PPA [\( n = 6 \); four nonfluent variant PPA (two had concomitant MND), one with semantic variant PPA, and one with logopenic variant PPA], and dementia with a memory presentation (\( n = 2 \)). For presymptomatic carriers, the clinical diagnoses of affected family members included: dementia only (\( n = 16 \)), dementia and/or MND (\( n = 8 \)), or MND only (\( n = 1 \)). As expected, symptomatic carriers were older, performed worse on the MMSE, and had higher CDR sum of boxes (CDR-SB) scores compared to both noncarriers and presymptomatic carriers (Table 1). The median age at disease onset in symptomatic carriers was 56 years but varied widely (17–76 years). The median disease duration at CSF collection was 2.8 years. Twenty-four symptomatic carriers died during follow-up with a median survival of 2.1 years after CSF collection (IQR: 1.0–4.2); the median follow-up interval of patients living at follow-up was 2.8 years (IQR: 1.2–4.5).

Poly(GP) levels

C9orf72 expansion carriers had higher poly(GP) levels than noncarriers (\( P < 0.001 \), Fig. 1A), which discriminated carriers from noncarriers with high accuracy (AUC 0.98, \( P < 0.001 \)), with a specificity of 100%, and a sensitivity of 96.6% (cut-off of \( >0.00 \) ng/mL, three expansion carriers fell below this cut-off). Poly(GP) levels trended higher in symptomatic carriers compared to presymptomatic carriers (\( P = 0.10 \)), and this observation became statistically significant upon correction for age and gender (post hoc Bonferroni corrected \( P = 0.04 \)). Poly(GP) levels did not differ between males and females, among presymptomatic carriers grouped by their relatives’ diagnoses, among clinical diagnoses of the symptomatic

4Available in 9 noncarriers, 18 presymptomatic and 28 symptomatic C9orf72 expansion carriers.
5Higher than in noncarriers.
6Available in 12 noncarriers, 25 presymptomatic and 62 symptomatic C9orf72 repeat expansion carriers.

NfL levels
CSF NfL levels were significantly higher in symptomatic carriers than in presymptomatic carriers and noncarriers (both P < 0.001, Fig. 1C, Table 1), and did not differ between the latter two groups. High CSF NfL levels differentiated symptomatic from presymptomatic carriers with a specificity of 96.0% and a sensitivity of 65.4% (cut-off at 1169 pg/mL, AUC 0.89, P < 0.001). Patients with concomitant MND at the time of CSF collection had higher NfL levels (median 3468 pg/mL) than those without concomitant MND (median 1819 pg/mL, P = 0.001, Fig. 1C and D). NfL did not differ between males and females, but did correlate with age in the total group and in each subgroup (entire cohort rs = 0.60, P < 0.001, carriers rs = 0.53, P < 0.001). NfL did not correlate with age at onset or disease duration at CSF collection, but negatively correlated with MMSE, and positively correlated with CDR and CDR-SB in all carriers combined (MMSE rs = −0.57, P < 0.001, CDR rs = 0.73, P < 0.001, CDR-SB rs = 0.72, P < 0.001), and in symptomatic carriers after stratification into presymptomatic versus symptomatic stage (MMSE rs = −0.42, P = 0.01, CDR rs = 0.39, P = 0.03, CDR-SB rs = 0.43, P = 0.03). High NfL levels were associated with a poorer prognosis in terms of survival [Fig 3A, hazard ratio on NfL tertiles of 4.2 (95% CI: 2.0–8.6), P < 0.001].

NfL did not correlate with poly(GP) in all carriers combined (P = 0.33, Fig. 3B), nor in presymptomatic or symptomatic carriers separately (P = 0.58 and P = 0.85, respectively). In an exploratory longitudinal analysis, NfL levels increased over time in some individuals but decreased in others, resulting in no significant longitudinal change at the group level (P = 0.89, n = 8, Fig. 2B). The different trajectories were not explained by evident differences in clinical characteristics.

Imaging associations
Associations of poly(GP) with grey matter volume
Although none of the correlations between grey matter volume and poly(GP) reached significance when corrected for multiple comparisons, trends of interest were noted.

Across all C9orf72 expansion carriers combined, higher levels of poly(GP) trended with lower frontal and cingulate grey matter volumes from the ROI analysis (Table 2); this trend remained after excluding FTD patients with concomitant MND. The voxel-wise grey matter analysis showed that poly(GP) tended to associate with regions of

Figure 1. Poly(GP) and NfL levels by clinical stage and diagnosis. (A) Poly(GP) levels were higher in presymptomatic and symptomatic C9orf72 expansion carriers than in healthy noncarriers, and higher in symptomatic carriers than in presymptomatic carriers after correction for age and gender. (B) Poly(GP) levels did not differ between different diagnoses. (C) NfL levels were elevated in symptomatic C9orf72 repeat expansion carriers when compared to noncarriers and presymptomatic carriers. (D) NfL levels were highest in symptomatic carriers with concomitant MND. Patients with concomitant MND at CSF collection are displayed as orange filled squares, those who developed MND after collection are displayed as blue filled triangles. Horizontal lines represent group medians. P-values from the ANCOVA analyses are displayed (corrected for age and gender) as follows: *P ≤ 0.05; **P ≤ 0.01; ***P ≤ 0.001; ns: not significant.

Figure 2. Longitudinal CSF poly(GP) and NfL levels. Longitudinal poly(GP) (A), but not NfL levels (B), increased significantly over time (P = 0.03 and P = 0.89, respectively) in presymptomatic (purple circles and connecting lines) and symptomatic (blue squares with connecting lines) C9orf72 repeat expansion carriers.

Figure 3. NfL predicts survival, does not correlate with poly(GP), and negatively correlates with frontal cortical volume. (A) Kaplan–Meier curve representing survival of symptomatic C9orf72 expansion carriers based on NfL levels; NfL levels were stratified into lowest (orange upper line), middle (blue middle line), and highest (purple lower line) tertiles; vertical ticks represent living patients censored at the date the patient was last known to be alive. Patients in the highest NfL tertile had the shortest survival. (B) NfL does not correlate with poly(GP) in presymptomatic (purple circles) or symptomatic (blue squares) C9orf72 expansion carriers, and (C) higher NfL levels significantly associated with lower frontal cortical volumes across presymptomatic (purple circles) and symptomatic (blue squares) C9orf72 expansion carriers combined (ROI analysis).
bilateral dorsomedial prefrontal and medial frontal cortices and lateral temporal cortex at \( P < 0.001 \) (Fig 4A, Table S2). Within these grey matter regions, bvFTD-MND and bvFTD showed the lowest grey matter intensities (Fig 4B). For the presymptomatic carriers, higher poly(GP) levels tended to associate with lower temporal ROI volume (Table 2), and lower volume in medial prefrontal cortex and scattered regions within lateral temporal cortices in the VBM analysis \((P < 0.001\), Fig 4C, Table S2). For symptomatic carriers, higher poly(GP) levels trended with lower cingulate grey matter ROI volume (Table 2), and with lower volume in a small dorsomedial frontal cluster in the VBM analysis \((P < 0.001\), Fig 4D).

**Associations of NfL levels with grey matter volume**

Higher CSF NfL levels were associated with lower frontal (Fig. 3C), temporal, and parietal ROI grey matter volumes in all carriers combined, but the latter two ROIs did not survive multiple comparisons correction (Table 2). In the VBM analysis, higher NFL levels were associated with lower grey matter volumes in the ventral and dorsomedial prefrontal cortex, ventral and dorsal insula, anterior cingulate, caudate, medial thalamus, and several other frontotemporoparietal regions \((P < 0.001\), Fig 5A and B, Table S2). At \( p_{fwe} < 0.05 \), higher NfL levels were associated with lower grey matter volume in small regions of dorsolateral prefrontal cortex, dorsal posterior insula, and the left caudate. In a subgroup analysis of presymptomatic carriers only, no significant correlations between grey matter ROIs and NfL emerged, and voxel-wise, NfL levels correlated with grey matter deficits in the inferior and middle frontal gyrus, pre- and postcentral gyrus, operculum, superior temporal gyrus, lateral parietal regions, and the caudate only at \( P < 0.001 \) (Fig 5C, Table S2) with no significant regions at \( p_{fwe} < 0.05 \). For

Associations between poly(GP) (first three columns) and NfL (last three columns) concentrations and different brain and grey matter ROIs in C9orf72 repeat expansion carriers, by means of linear regression corrected for age, gender, and scanner. \( P \)-values below 0.05 are bolded. NfL, neurofilament light chain; ROI, region of interest.

1Significant after correction for multiple testing (Bonferroni corrected \( P \)-value: \( P < 0.004 \)).
symptomatic carriers, NfL significantly correlated with frontal cortex in the ROI analysis, and the VBM showed associations with bilateral dorsolateral prefrontal cortex, anterior and mid cingulate cortex, dorsal insula, pre- and postcentral gyrus, medial parietal regions and the caudate ($P < 0.001$, Fig 5D), with no significant regions at $p_{fwe} < 0.05$.

**Discussion**

In this study, CSF poly(GP), NfL, and grey matter volumes were determined in a cohort of 89 C9orf72 repeat expansion carriers to examine associations among these measures. Poly(GP) was detected in CSF of both presymptomatic and symptomatic C9orf72 expansion carriers, and not detected in noncarriers. In contrast, we found high NfL levels exclusively in symptomatic carriers, while levels in presymptomatic carriers remained similar to healthy noncarriers. Higher NfL levels correlated with greater disease severity as well as shorter survival. In addition, higher NfL levels associated with lower grey matter volumes in regions known to show smaller grey matter volume in presymptomatic and symptomatic carriers, but for poly(GP), only trends were observed. As such, CSF NfL and poly(GP) capture abnormalities during different phases of the disease, and may thus serve as...
complementary biomarkers for disease detection and future treatment monitoring.

**Poly(GP) is a highly sensitive and specific biomarker for C9orf72 expansion carriers**

We showed that CSF poly(GP) has high power to differentiate C9orf72 expansion carriers and noncarriers, consistent with previous reports.\(^{10,11,14}\) Interestingly, poly(GP) levels were undetectable in three C9orf72 expansion carriers, who had various clinical presentations, including a presymptomatic individual, a bvFTD patient, and a PPA patient. Future studies may inform whether alternative detection strategies with increased sensitivity would detect poly(GP) in these individuals, or whether their poly(GP) levels are truly negligible. Should postmortem tissue become available for these individuals and others, it would be of particular interest to evaluate how CSF poly(GP) levels compare to the frequency of DPR protein pathology and levels of repeat-containing transcripts in the brain. As in previous studies,\(^ {11,14}\) we found that poly(GP) was detectable in CSF from presymptomatic C9orf72 expansion carriers, suggesting that DPR protein production emerges prior to neurodegeneration and that poly(GP) can be actively released from putatively healthy neurons. This notion is supported by in vitro experiments that show that DPR proteins are secreted from cultured cells.\(^ {11,29}\) Reports of autopsy studies in C9orf72-patients have also described widespread DPR protein pathology prior to the formation of TDP-43 inclusions.
and neuronal loss. These studies provide converging evidence that poly(GP) expression arises early in the lifespan of C9orf72 expansion carriers.

**Poly(GP) levels are higher in symptomatic C9orf72 expansion carriers compared to presymptomatic carriers**

Symptomatic carriers had higher poly(GP) levels compared to presymptomatic carriers after correcting for age and gender. In parallel, we found a modest increase in CSF poly(GP) over time in a small subset of 10 C9orf72 expansion carriers, most frequently in the presymptomatic subjects. In contrast, other studies had not identified a significant difference in poly(GP) levels between presymptomatic and symptomatic carriers, nor an increase in poly(GP) levels over time. The time interval between repeated CSF collections was longer in the present exploratory analysis, suggesting that changes in poly(GP) might only emerge over longer periods. Measuring poly(GP) in larger cohorts over extended time periods as individuals convert from the presymptomatic to symptomatic phase will further help elucidate the temporal trajectory of poly(GP), and whether levels change relative to symptom onset.

We found that poly(GP) levels did not differ among clinical phenotypes, and did not correlate with age at disease onset or survival. Although there is a possibility of a type II error (i.e., a false-negative association) given that several clinical subgroups had a small sample size, these data are in line with the lack of associations between clinical phenotypes and other C9orf72-associated features, such as repeat size and RNA foci burden. While we were unable to examine correlations between CSF poly(GP) and repeat length in blood because repeat length data were not available, such an analysis would likely be complicated given the substantial variation in repeat sizes among various tissues from the same individual. Furthermore, a previous study has shown no association between CSF poly(GP) and repeat length in blood, and we observed no association between poly(GP) levels in the cerebellum or frontal cortex and repeat length in these regions. Nonetheless, examining associations between antemortem CSF poly(GP) and repeat size, poly(GP) levels, and levels of other DPR proteins in various neuroanatomical regions will be of interest when postmortem tissue becomes available from a suitable number of cases. Also, as arginine-containing DPR proteins, poly(GR) and poly(PR), are considered to be highly toxic, it is possible that elevated levels of these DPR proteins may correlate with clinical features and measures of neurodegeneration. The development of immunoassays quantifying these proteins remains technically challenging, but may lead to more insights into C9orf72 disease mechanisms.

**Nfl is normal in presymptomatic C9orf72 expansion carriers and is elevated in symptomatic carriers**

Determining symptom onset in C9orf72 repeat expansion carriers is notoriously challenging. Presymptomatic carriers have a high incidence of psychiatric symptoms overlapping with bvFTD symptomatology, and some carriers have a mild, slowly progressive prodromal phase spanning several decades. Consequently, surrogate endpoints reflecting neurodegeneration are critical for assessing disease onset and the efficacy of therapeutic interventions. Our data show that NfL is elevated during the symptomatic phase of C9orf72-associated dementia and correlate with indicators of disease severity (i.e., MMSE, CDR, and CDR-SB), survival, and grey matter atrophy, consistent with other studies of NfL in sporadic and genetic FTD. In mouse models, NfL also correlates with disease severity, specifically with the burden of α-synuclein, tau, or β-amyloid inclusions, and NfL levels are attenuated with treatment. Thus, NfL could be utilized in clinical trials to stratify patients into more homogeneous groups with respect to disease severity and to assess the neuroprotective effect of therapeutic interventions. Furthermore, the strong association between CSF NfL and survival supports the use of NfL as a prognostic marker. NfL can now be reliably measured in serum and plasma, which is collected less invasively than CSF, making it promising for clinical use, especially when frequent measures are needed.

Our small longitudinal study of CSF NfL levels did not show consistent changes over the time intervals assessed. Previous studies on ALS patients reported stable NfL levels, but showed an increase over time for a subset of patients with a rapid disease progression. Serum NfL levels have also been shown to progressively increase in sporadic PPA patients. The discrepancy between our and previous findings could be attributable to the small size of our longitudinal cohort, and the range of clinical phenotypes and disease durations among individuals at the time of sample collection. Given that the rate of neurodegeneration can differ not only throughout the course of disease but also among patients, additional longitudinal studies on larger cohorts of C9orf72 expansion carriers are needed to fully understand the temporal trajectory of NfL in relation to clinical changes.

**Relationships between poly(GP) and indicators of neurodegeneration**

This study did not show a significant relationship between poly(GP) levels and indicators of neurodegeneration, as reflected by NfL levels and grey matter volumes. Similarly,
previous studies show no correlation between poly(GP) and NfL, nor neurofilament heavy chain (a different neurofilament subunit) in C9orf72-associated ALS. Because previous studies have shown lower grey matter volumes in both presymptomatic and symptomatic carriers compared to controls, we had hypothesized that higher levels of poly(GP) might be associated with lower grey matter volumes in C9orf72-targeted regions. We found a trend toward higher poly(GP) with lower frontal and cingulate volume in our ROI analysis. In parallel with the ROI analysis, the voxel-wise analysis showed that certain sparse regions of lower grey matter volumes tended to associate with higher poly(GP), which included regions in the bilateral dorsolateral prefrontal, medial frontal, and lateral temporal cortices. Although higher poly(GP) levels showed a relatively weak association with lower grey matter volumes in our analyses, the regions identified include those atrophied in C9orf72-associated FTD patients, and show reduced volume in presymptomatic C9orf72 expansion carriers.

Interestingly, our subgroup analysis of presymptomatic carriers showed a trend for association between higher poly(GP) and reduced bilateral medial orbitofrontal cortex, but symptomatic carriers showed only sparse regions that trended toward an association with high poly(GP). One potential explanation for this result is that DPR accumulation may arise focally during the presymptomatic phase and become widespread during the symptomatic phase, thus attenuating any potential relationship between grey matter atrophy and poly(GP) during the symptomatic phase. Overall, our results suggest that higher poly(GP) levels may be associated with some key foci in C9orf72-associated regions, particularly for presymptomatic carriers, but poly(GP) levels are not a marker for neurodegeneration per se.

Higher NfL levels are associated with grey matter deficits

Elevated NfL levels were associated with lower grey matter volume based on both types of analysis. These data reveal vulnerable neuroanatomical structures during the presymptomatic and symptomatic stages, which include ventral and dorsomedial prefrontal cortex, ventral and dorsal insula, anterior cingulate, caudate, and the medial thalamus. These regions are highly anatomically congruent with atrophy patterns found in C9orf72-associated frontotemporal dementia. Notably, several studies confirmed that the medial thalamus is a region affected across C9orf72 expansion carriers, even during the presymptomatic phase. Interestingly, our subgroup analysis of presymptomatic carriers showed that higher NfL levels were associated with smaller bilateral frontal and caudate volumes, which may indicate that these regions are among the earliest regions of neurodegeneration, but longitudinal presymptomatic studies are needed to test this hypothesis.

Conclusion

The strength of this study is the use of a multimodal approach combining two CSF biomarkers with quantitative structural imaging metrics to investigate the relationship between poly(GP) and indicators of neurodegeneration in a large cohort of presymptomatic and symptomatic C9orf72 expansion carriers. To the best of our knowledge, this is the largest study thus far on poly(GP) in C9orf72-associated FTD, and the first in examining associations between DPR protein levels and grey matter volume. We used two neuroimaging methods: ROI analyses, the metrics of which are reliable and can be readily analyzed by clinical groups, and voxel-wise analyses, which can refine grey matter deficits in a more granular fashion. We show that poly(GP) and NfL are promising complementary biomarkers that capture the effects of the C9orf72 repeat expansion during different phases, and demonstrate different relationships with grey matter volume. While poly(GP) may display less utility as a prognostic or staging biomarker, it shows great promise as a pharmacodynamic biomarker for therapeutic approaches that target G4C2 RNA in preclinical models. Importantly, poly(GP) levels are detectable in presymptomatic carriers and would thus make the inclusion of this population in clinical trials more feasible. Because NfL reflects neurodegeneration and is associated with grey matter atrophy, it will be most useful for monitoring disease severity, and predicting disease progression and survival.

Acknowledgments
